ABSTRACT

In recent years, biotechnological breakthroughs have led to identification of complex and unique biologic features associated with carcinogenesis. Tumor and cell-free DNA profiling, immune markers, and proteomic and RNA analyses are used to identify these characteristics for optimization of anticancer therapy in individual patients. Consequently, clinical trials have evolved, shifting from tumor type-centered to gene-directed, histology-agnostic, with innovative adaptive design tailored to biomarker profiling with the goal to improve treatment outcomes. A plethora of precision medicine trials have been conducted. The majority of these trials demonstrated that matched therapy is associated with superior outcomes compared to non-matched therapy across tumor types and in specific cancers. To improve the implementation of precision medicine, this approach should be used early in the course of the disease, and patients should have complete tumor profiling and access to effective matched therapy. To overcome the complexity of tumor biology, clinical trials with combinations of gene-targeted therapy with immune-targeted approaches (e.g., checkpoint blockade, personalized vaccines and/or chimeric antigen receptor T-cells), hormonal therapy, chemotherapy and/or novel agents should be considered. These studies should target dynamic changes in tumor biologic abnormalities, eliminating minimal residual disease, and eradicating significant subclones that confer resistance to treatment. Mining and expansion of real-world data, facilitated by the use of advanced computer data processing capabilities, may contribute to validation of information to predict new applications for medicines. In this review, we summarize the clinical trials and discuss challenges and opportunities to accelerate the implementation of precision oncology.

Background

The rapidly expanding body of knowledge about the roles of genomics and the immune system in cancer has enabled the development of therapies targeted to specific molecular alterations or other biologic characteristics, such as those implicated in immune suppression. However, genomics has also revealed a complicated reality about malignancies that requires a major shift in the therapy paradigm: away from tumor type-centered and toward gene-directed, histology-agnostic treatment, which is individualized for each patient on the basis of biomarker analysis. This paradigm shift is reflected by the emergence of precision medicine trials with innovative design [1–21]. Next-generation sequencing (NGS) of advanced cancers has demonstrated that genomic alterations do not fall neatly into categories defined by the tumor organ of origin. Furthermore, metastatic tumors harbor tremendously complex and individually unique genomic and immune landscapes [22,23]. Therefore, in order to target malignancies with

“precision,” treatment needs to be personalized.

Historically, phase II and III oncology clinical trials have measured outcomes histologically, but histological assessment cannot always capture the effects of gene-targeted agents or immunotherapy. Precision medicine approaches analyze patients’ circulating DNA (liquid biopsy), as well as immune markers and other biologic features, to assess efficacy and make treatment decisions. Genomic biomarkers have been the most successful to date, but other biomarkers, including protein assays and transcriptomics, are being developed and tested [13,24,25]. Several molecular alterations have been identified using sequencing and high-throughput technologies and have led to the approval of targeted agents by the Food and Drug Administration (FDA) [26,27]. Importantly, in recent years, the precision medicine paradigm has embraced immunotherapy and its interaction with genomics, as genomic characteristics, such as mismatch repair gene defects, are critical predictors of checkpoint blockade response [28–30].

Herein, we review the rapid evolution of precision medicine in

oncology and, in particular, the challenge and opportunity that genomic science has revealed *vis-à-vis* the need for “N-of-1” treatments. This treatment model does not conform to either canonical trial design or clinical practice, which seek to find commonalities between patients and treat them alike; instead, its goal is to provide optimized individualized treatment for each patient on the basis of biomarker analysis.

History

Survival improvement with gene- or immune-directed therapy was accelerated by several major discoveries. In particular, the introduction of imatinib mesylate (Abl tyrosine kinase inhibitor) for patients with Philadelphia chromosome [t(9;22)]-positive chronic myelogenous leukemia producing the enzymatically aberrant Bcr-Abl [31,32] resulted in near-normal life expectancy for patients with this previously fatal leukemia.

In 2001, the human genome was sequenced [33]. Although this milestone represented an arduous and tremendously expensive endeavour, both the price and time required for sequencing have decreased precipitously, with technology advancing in a manner unparalleled in human history. A plethora of first- and second-generation precision medicine trials have since been conducted (Tables 1 and 2). They include, but are not limited to, the first pan-histology biomarker-driven trial using mostly protein markers [1], the prospective molecular profiling of patients with advanced cancer in the phase I clinical trials setting (IMPACT trial) [2,4], the SHIVA randomized trial [5], trials assessing customized combinations [6,12], and trials including transcriptomics [13].

Innovative clinical trial designs for precision medicine

Traditionally, oncology trials are drug-centered, aiming to identify common attributes among patients (e.g., their tumor type or, more recently, a shared genomic abnormality) and fit them into a trial with a specific drug regimen. The large variability in genomic subgroups, microenvironment, baseline characteristics, comorbidities, and other covariates resulted in tumor-specific clinical studies encompassing a tremendously heterogeneous population in histology-specific, gene-agnostic trials. Phase III randomized trials were often critical for regulatory approval of a novel agent/regimen, especially since the anti-tumor activity of a new drug/regimen was frequently only marginally better than the comparator arm (usually, conventional therapy), perhaps because the regimen was effective in only a small subgroup of the diverse population represented by any specific histology.

Basket, umbrella, platform, octopus, and master protocols

More recently, basket designs have emerged that target a common genetic defect [27]. The 75% objective response rate noted across tumor types with larotrectinib, which targets *NTRK* fusions, best exemplifies the potential of the basket gene-directed, histology-agnostic model, though other single-gene targets have proven much less responsive [27]. Umbrella trials involve a single histology and different treatments based on the genomic alterations in patient subgroups [34]. Other trial designs include platform trials, which use a single analytic technique, such as NGS, to identify genomic or other biomarkers in tumors with multiple histologies; octopus trials (also referred to as “complete phase I trials”) that have multiple arms testing different combinations featuring a particular drug; and master protocols, which encompass trials with several histologic arms (previously, “broad phase II trials”) or multiple platform, basket, or umbrella trials or sub-trials [2–4,6]. Randomization has also evolved, with the emergence of Bayesian adaptation, which allows dynamic modifications of randomization based on small numbers of patients and real-time outcomes.

From drug-centered to patient-centered studies

The ultimate goal of precision medicine is an individualized, patient-centered (rather than drug-centered) trial based on the best available biomarkers. In “N-of-1” trials, each patient’s treatment is considered separately on the basis of molecular, immune, and other biologic characteristics. These trials involve customized drug combinations tailored to individual patients [12]. Determining efficacy in “N-of-1” trials requires assessing the “strategy” of matching patients to drugs, rather than treatments, which differ from patient to patient.

Real-world data

With advanced computer data “processing” capabilities, real-world registries and data mining are expanding. Two drug approvals by the FDA were based, at least in part, on such data: pembrolizumab for any solid tumor with a mismatch repair gene defect (<https://www.fda.gov/Drugs/InformationOnDrugs/ApprovedDrugs/ucm5600470.htm>) and palbociclib for male breast cancer (<https://www.fda.gov/NewsEvents/Newsroom/PressAnnouncements/ucm635276.htm>). The stunning possibility exists that real-world data, if confirmed to accurately portray the anticipated results of prospective trials, will dramatically accelerate the drug approval process.

Genomic and other biomarkers

Genomics has been the cornerstone of precision medicine studies. Beyond genomics, RNA and protein profiling, with proteins being the effectors of signaling, also appear to be important in mediating biologic impact. Interestingly, matching patients to drugs on the basis of genomics has proven more effective in improving outcome than matching on the basis of protein assays, perhaps for technical reasons [24]. Despite the current practical limitations, protein and transcript assays may provide essential information when integrated with genomics [13]. Recently, panels that incorporate immune signatures, based on DNA, RNA, and/or proteins, have also gained clinical significance [35].

Genomics

Given the advances in NGS technologies and the large number of laboratories in the US that perform Clinical Laboratory Improvement Amendments (CLIA)-certified NGS, optimization of the accuracy, reproducibility, and standardization of sequencing methods; variant annotation; and data interpretation is critical. Guidelines for the validation of NGS panels [36] and the interpretation and reporting of genomic variants have been developed [37]. Although whole-genome sequencing is not yet the standard practice in the clinic, the FDA has approved two NGS panels that include hundreds of genes [38].

Most genomic sequencing involves tissue, but blood-derived circulating tumor DNA (ctDNA), circulating tumor cells [39], and exosomes [40] are increasingly used, with the latter two reflecting the contents of live cells.

Blood-derived cell-free DNA analysis

Clinical-grade ctDNA testing, which is non-invasive and reflects tumor heterogeneity (because tumor DNA may be leaked into the bloodstream from multiple metastatic lesions), is increasingly being used to select anti-cancer therapy and to monitor subclone dynamics during treatment [41,42]. The discordance noted in some cases between results of ctDNA testing and tumor tissue genotyping analysis [43] could reflect technical issues but might be attributable to the following biologic reasons: (i) tumor NGS measures genomics in the small piece of tissue biopsied while ctDNA assesses shed DNA from multiple sites; (ii) ctDNA is associated with tumor load and can be detected at low levels.

Table 1
Examples of Precision Medicine Trials: Design and Outcomes.

Year First/Last author	Trial name	Trial type	No of pts screened (N)	Proportion of pts. matched	Biomarker(s)	Outcome	Institute(s)	Comments
Diverse treatment-refractory tumor types								
2010 [1] Von Hoff D Penny R	BiSGrove	Prospective, navigational	86	77%	IHC, FISH, microarray	27% of 66 matched pts had a PFS2/PFS1 ratio* ≥ 1.3 (95% CI, 17% to 38%; $p = 0.007$).	US (9 sites)	
2012 [2] Tsimberidou A Kurzdock R	IMPACT, first cohort	Registry type, Navigational	1144	15%	PCR-based genomics, 9 genes	Matched vs unmatched RR, 27% vs. 5% ($p < 0.0001$), TTF: median, 5.2 vs. 2.2 mos ($p < 0.0001$) OS: median, 13.4 vs. 9.0 mos ($p = 0.017$)	MD Anderson Cancer Center	
2014 [3] Tsimberidou A Berry D	IMPACT, second cohort	Registry type, navigational	1276	11%	PCR-based genomics, 18–50 genes	Matched vs unmatched RR, 11.9% vs. 5% ($p < 0.0001$), PFS: median, 3.9 vs. 2.2 mos, ($p = 0.001$); OS: median, 11.4 vs. 8.6 mos ($p = 0.04$)	MD Anderson Cancer Center	2-month landmark analyses, matched therapy group: OS, responders 30.5 months vs. 11.3 months for non-responders ($p = 0.01$).
2017 [4] Tsimberidou AM Kurzdock R	IMPACT, third cohort	Registry type, navigational	1436	27%	PCR-based genomics and NGS, 11 to 182 genes	Matched vs unmatched Higher rates of ORR ($p = 0.0099$), TTF ($p = 0.0015$), and OS ($p = 0.04$)	MD Anderson Cancer Center	
2015 [5] Le Toumeau Paolletti X	SHIVA	Prospective, randomized	741	13%	Targeted NGS, ~50 genes	PFS not improved with matched therapy ($p = 0.41$)	Institut Curie, 8 French sites	~80% of patients received single- agent hormone modulators or everolimus
2016 [6] Schwaederle M Kurzdock R	PREDICT	Registry type	347	25%	NGS, 182 or 236 genes	Matched vs unmatched Higher rates of SD ≥ 6 months/PR/CR ($p = 0.02$) and PFS ($p < 0.04$). Higher matching scores correlated with better OS: 15.7 vs 10.6 mos ($p = 0.04$)	University of California San Diego	
2016 [7] Wheler JJ Kurzdock R	MD Anderson Personalized Cancer Therapy Initiative	Prospective, navigational	500	24%	NGS, 236 genes	Higher matching scores correlated with higher rates of SD ≥ 6 months/PR/CR ($p = 0.024$), TTF ($p = 0.0003$), and OS ($p = 0.05$)	MD Anderson Cancer Center	
2016 [8] Stockley TL Bedard PL	IMPACT/ COMPACT	Prospective	1893	5%	Hot spot panel, 23 genes	Matched vs unmatched Higher ORR: 19% vs 9%, ($p = 0.026$).	Princess Margaret, Canadian centers	
2017 [9] Massard C Soria JC	MOSCATO	Prospective	1035	19%	Targeted NGS, 40–75 genes; aCGH; RNAseq	PFS2/PFS1 ratio* was > 1.3 in 33% (63/193) of patients	Institut Gustave Roussy	
2018 [10] Hainsworth JD Kurzdock R	MyPathway	Prospective, Phase 2 basket	251	Not available	Genomic testing via any CLIA lab	Matched patients, ORR: All, 23% <i>HER2</i> -altered, 38% <i>BRAF</i> -altered, 43% RR = 13% (23 of 182 treated)	Multiple sites, Genentech	251 patients enrolled; 230 were treated; however, how many were screened pre-enrollment is unknown
2019 [11] Tredan O Blay JY	Profilor	Prospective	2579	6%	NGS, 69 genes		Four institutes (France)	
2019 [12] Sicklick J Kurzdock R	I-PREDICT	Prospective, navigational	149	49%	NGS, 315 genes; cDNA; PDL1 IHC	Higher matching scores correlated with increased rates of SD ≥ 6 months/PR/CR: 50% vs 22.4% ($p = 0.028$), PFS ($p = 0.0004$), and OS ($p = 0.038$)	University of California San Diego and Avera	First trial to administer customized combination therapy ("N-of-1" matching)
2019 [13] Rodon J Kurzdock R	WINTER	Prospective, navigational	303	35%	NGS, 236 genes; transcriptomics	Higher matching scores correlated with longer PFS ($p = 0.005$) and OS ($p = 0.03$)	Five countries (Spain, Israel, France, Canada, US)	First solid tumor trial to include transcriptomics
Specific tumors—Lung								
2011 [14] Kim ES Hong WK	BATTLE	Prospective, adaptive, randomized	255	Not available	11 biomarkers	8-week disease control rate, 46%	MD Anderson Cancer Center	It is unclear how many patients were screened before consent

(continued on next page)

Table 1 (continued)

Year First/Last author	Trial name	Trial type	No of pts screened (N)	Proportion of pts. matched	Biomarker(s)	Outcome	Institute(s)	Comments
2014 [15] Kris MG Bunn PA	Lung cancer mutation consortium	Prospective	1537	17%	Multiplex genotyping, 10 genes	Improved OS with matched vs unmatched therapy (p = 0.006)	14 US sites	
2016 [16] Aisner D Kwiatkowski DJ	Lung Cancer Mutation Consortium II	Prospective	904	12%	NGS, minimum of 14 genes	Improved survival with matched therapy (p < 0.001)	16 sites	
2016 [17] Papadimitrakou V Herbst RS	BATTLE-2	Prospective, adaptive, randomized	334	Non-applicable	ALK, FISH, EGFR, and KRAS Sanger sequencing	KRAS alterations: longer PFS without erlotinib (p = 0.04); KRAS wild-type tumors: longer OS on erlotinib (p = 0.03)	MD Anderson Cancer Center	
Specific tumors—Breast								
2012 [18] Esserman LJ Hylton N	I-SPY 1	Neoadjuvant, correlative	237	Non-applicable	IHC	pCR differs by subset	Multiple US sites	Aim was to develop biomarkers of response to conventional therapy
2015 [19] Andre F Bonnefoi H	SAFIR01/ UNICANCER	Prospective	423	13%	Sanger sequencing (2 genes: <i>PIK3CA</i> and <i>AKT</i>); aCGH	Matched group, ORR 9%	18 centers in France	
2016 [20,21] Park JW Berry DA Rugo HS Esserman LJ	I-SPY 2	Phase 2 adaptive design, neoadjuvant	Non- applicable	Non-applicable	IHC, Mammamprint	Improved pCR rates in 2 study arms with drug addition: HER2+, hormone receptor-negative: neratinib plus standard therapy (N = 115) vs standard therapy (N = 78): 56% vs 33% Triple-negative: veliparib plus carboplatin (N = 72) with standard therapy vs standard therapy (N = 44): 51% vs 26%	Quantum-Leap Healthcare (US sites)	Results for 2 arms of I-SPY-2 study available
Specific tumors—Gastric								
2019 [120] Lee J WK Kang	VICTORY	Prospective	772	14%	NGS, IHC, PDL1, MMR and EBV status	Improved PFS and OS with matched vs unmatched therapy (p < 0.0001)	Republic of Korea	The trial included 10 phase II trials that operated independently (based on eight biomarkers)

*PFS2/PFS1 ratio is defined by the PFS on the trial versus the PFS on the therapy immediately preceding the trial; in general, PFS is shorter with every subsequent therapy.

**Only studies published as manuscripts, not just as abstracts, included.

Blood-derived circulating tumor cell (CTC) analysis

The presence of CTCs, which are epithelial tumor cells, has been independently associated with worse survival in several types of cancer [44–46]. For example, in a prospective, multicenter, double-blind study, the number of CTCs in patients with untreated metastatic breast cancer correlated with shorter progression-free survival (PFS) and overall survival (OS) [44]. CTCs may also be a predictive biomarker for chemotherapy and immunotherapy [45,47]. However, the use of CTCs in clinical practice has not been fully established [48]. Finally, serial CTC analyses might enable real-time surveillance of the disease. A comparative study of five prospective randomized phase III trials in 6081 patients with metastatic castration-resistant prostate cancer assessed the prognostic value of CTCs compared to prostate-specific antigen [49]. CTC ≥ 0 at baseline and at week 13 from treatment initiation was associated with OS. The investigators demonstrated that CTC monitoring was a robust and meaningful response endpoint for early-phase clinical trials in this setting [49].

Transcriptomics

Transcriptomics refers to the study of RNA transcripts and their function. Transcriptomic analysis is performed using high-throughput technologies, including microarrays and RNA sequencing and it is a potentially valuable tool, particularly when there is discrepancy between genomic alterations and gene expression. Transcriptomics are utilized to identify prognostic and predictive gene expression signatures [50,51], to explore miRNAs and their role in mRNA regulation [52,53] and to identify the tissue of origin in cancer of unknown primary [54–56]. The first solid tumor precision medicine trial to use transcriptomics in the clinic—WINTHER—compared RNA expression in tumors to that in adjacent normal tissue and demonstrated that transcriptomics increased the number of patients that could be matched to therapy [13]. Comparing tumor to normal tissue from the same patient may be necessary because of the large inter-patient variability in normal RNA expression. Other investigators have also used transcriptomics to select targeted treatments in patients with advanced solid tumors [57,58]. Challenges that prevent extensive use of transcriptomic biomarkers are degradation and fragmentation of RNA in formalin-fixed, paraffin-embedded tissue samples, complexity of required bioinformatic analysis of profiling data and low reproducibility of the results.

Proteomics

Proteomic analysis using immunohistochemical and other assays of tumors from patients with refractory metastatic cancer led to the identification of molecular targets that could guide therapeutic decisions and was associated with longer PFS compared to the patients' PFS with their prior therapy (using patients as their own controls) [1]. Proteomic assays are used in clinical practice to identify prognostic or predictive biomarkers for targeted treatments (hormone receptor expression, HER2 overexpression, ALK expression). However, the weaker correlation of proteomic markers, compared to genomic markers, with clinical outcomes suggests that technical issues should be addressed [24]. In a meta-analysis of phase 1 clinical trials of small molecules that used a genomic biomarker vs. those that used a protein biomarker, the median response rate was 41% vs. 25%, respectively ($p = 0.05$) [24]. Ongoing studies with targeted therapies include correlative analyses using peripheral blood and tumor tissue to identify proteomic biomarkers of response or resistance to treatment (LEEomic, NCT03613220 and BABST-C, NCT03743428).

Immunotherapy and cellular therapy

By reactivating the innate immune antitumor response, immunotherapy has provided a major breakthrough in oncology

treatment [28,59]. Several novel approaches are currently being explored: checkpoint blockade, oncolytic viruses, cell-based products, modified cytokines, CD3-bispecific antibodies, vaccine platforms, and adoptive cell therapy [60].

Checkpoint blockade

There are seven FDA-approved checkpoint inhibitors: ipilimumab, pembrolizumab, nivolumab, avelumab, cemiplimab, durvalumab, and atezolizumab. Selected patients with advanced disease have remarkable response, including durable complete remission (CR). Despite the significant benefit noted in patients with diverse tumor types treated with checkpoint inhibitors, approximately 80% of patients across cancers do not experience beneficial effects. In the era of precision medicine, genomics, transcriptomics and other technologies are employed for the identification of biomarkers that predict benefit from immunotherapy. Interestingly, biomarkers predicting checkpoint inhibitor responsiveness are genomic: high tumor mutational burden (TMB) [28,59,61], mismatch gene repair defects resulting in high microsatellite instability (MSI-H) (and, thus, high TMB) [29,62], *PBRM1* alterations [63,64], and *PDL1* amplification [65]. Specifically, TMB has been shown to predict clinical benefit from checkpoint inhibitors [28]. In an analysis of 151 of 1638 patients who were treated with immunotherapeutic regimens and had TMB evaluation, high (≥ 20 mutations/mb) TMB was independently associated with significant improvement in PFS and OS compared to low to intermediate TMB [28]. Other studies have however questioned the use of TMB as a biomarker [66,67].

Given its strong association with response to immunotherapy, MSI-H is an established biomarker for response to checkpoint inhibitors [68,69]. MSI-H tumors have high TMB, often accumulating > 1000 non-synonymous genomic mutations, leading to tumor-specific proteins, known as neoantigens. Due to high clinical benefit rates, immunotherapeutic regimens have been approved by the FDA for the treatment of patients with advanced MSI-H colorectal cancer [70–72] or MSI-H tumors, irrespective of the organ of origin [73]. Finally, defects in DNA proofreading proteins polymerase δ (POLD1) and polymerase ϵ (POLE) lead to increased TMB and are associated with response to immunotherapy [59,74,75]. For instance, of 4 patients with non-small cell lung cancer with deleterious mutations in POLD1 and POLE (whole-exome sequencing, [WES]), 3 patients with the highest TMB responded to pembrolizumab [59]. Defects in other DNA repair systems might also be associated with response to immunotherapy. The predictive role of homologous recombination deficiency (HRD) is being evaluated in various tumors, including breast and ovarian cancer. Early phase clinical trials demonstrating that these patients may benefit from the addition of immunotherapy to poly ADP-ribose polymerase (PARP) inhibitors, should be confirmed with additional studies [76,77].

Furthermore, *PBRM1* molecular alterations are evaluated as genomic biomarkers predicting checkpoint inhibitor responsiveness. Specifically, *PBRM1* alterations were evaluated in a study of 35 patients with metastatic renal cell cancer treated with anti-programmed death-1 (PD-1) regimens [63]. WES revealed loss-of-function (LOF) mutations in the *PBRM1* gene that predicted response to immunotherapy. Notably, the *PBRM1* gene encodes for a protein of the chromatin remodeling complex, possibly interfering with hypoxia, and immune signaling pathways [63].

Another biomarker that predicts benefit from immunotherapy is PD-L1 amplification [65]. In a retrospective analysis, this marker was identified in 0.7% (843 of 118,187) patients of various tumor types and it did not always correlate with PD-L1 expression. Six of 9 (66.7%) patients with PD-L1-amplified solid tumors had an objective response to checkpoint inhibitors, and their median PFS was 15.2 months [65]. PDL1 expression, assessed by immunohistochemistry on tumor cells or immune cells can be used as a response marker, albeit a suboptimal one [78]. Approximately 20% of FDA approvals of immunotherapeutic agents are based on companion PD-L1 diagnostic testing [79].

Genomic markers may also predict resistance—loss of JAK2 and beta 2 microglobulin mutations [80]—or hyper-progression (accelerated progression) after checkpoint blockade—*MDM2* amplification and *EGFR* alterations [81]. WES of tumor tissue from 4 patients with advanced melanoma whose disease was resistant to anti-PD1 therapy, demonstrated LOF mutations in genes involved in interferon-receptor signaling and in antigen presentation (JAK1/2, β 2-microglobulin) [80]. Importantly, PTEN loss is associated with resistance to immunotherapy in patients with melanoma, suggesting that targeting the PI3K/AKT/mTOR pathway may overcome resistance to immunotherapy [82]. In our opinion, it is plausible that when PI3K/AKT/mTOR pathway alterations or PTEN loss are the key drivers of the disease, immunotherapy may have limited, if any, antitumor activity. Similarly, STK11 mutations and β -catenin pathway alterations are reportedly associated with resistance to immunotherapy [83,84].

In summary, the available biomarkers are insufficient to adequately predict response to immunotherapy. Novel strategies may enhance our ability to identify biomarkers longitudinally, incorporating ctDNA analysis [85] or tumor tissue immune, genomic, transcriptomic, and proteomic analysis.

Adoptive cell therapy

Adoptive cell therapy (ACT) is an innovative personalized treatment approach that enhances a patient's immune system leading to specific tumor cell killing. Immune cells derived from a patient's blood or tissue are expanded *in vitro* and then reinfused into the patient. These immune cells may be reprogrammed to recognize tumor-specific antigens [60,86]. Types of ACT include tumor-infiltrating lymphocyte (TIL) therapy, chimeric antigen receptor (CAR) T-cell therapy, engineered T-cell receptor (TCR) therapy and natural killer (NK) cell therapy.

TILs

ACT of TILs is based on the use of T-cells that have infiltrated a patient's tumor. Autologous cells are being harvested and administered to patients after their expansion and activation. This approach has shown promising results in metastatic melanoma [87–90], nasopharyngeal, and cervical carcinoma [91,92]. In three sequential clinical trials in patients with metastatic melanoma who had failed standard therapy, the use of autologous TILs was associated with objective response rates of 49%, 52%, and 72%, respectively; durable CRs were reported in 22% (20 of 93) of patients; and clinical benefit was observed irrespective of prior therapy [87]. Ongoing clinical trials assess the role of TIL therapy in various solid tumors (NCT03645928, NCT03935893, NCT03108495, NCT03083873).

CAR T-cells

CAR T-cells are a type of adoptive T-cell therapy in which autologous T-lymphocytes are genetically engineered to recognize the antigens expressed on malignant cells [93]. Adoptive T-cell therapy has resulted in remarkably high rates of durable CR in hematologic malignancies, including in patients with refractory disease. Therefore, the FDA has approved CAR T-cells for the treatment of pediatric patients and young adults with relapsed/refractory B-cell precursor acute lymphoblastic leukemia (Kymriah™, <https://www.fda.gov/drugs/resources-information-approved-drugs/fda-approves-tisagenlecleucel-adults-relapsed-or-refractory-large-b-cell-lymphoma>) and adult patients with relapsed/refractory diffuse large B-cell lymphoma (Yescarta™, <https://www.fda.gov/vaccines-blood-biologics/cellular-gene-therapy-products/yescarta-axicabtagene-ciloleucel>). CAR T-cells are currently being evaluated in solid tumors [94,95].

TCR therapy

This approach uses T-cell receptor (TCR) engineered T-cells, and involves retroviruses that enable integration of new TCR transgene targeting antigens, which are expressed at high levels on different cancers into the genome of T-cells [96]. TCR therapy has been assessed in hematologic and solid malignancies [97–101]. Current trials evaluate treatment-associated toxicity, binding affinity to tumor antigens and efficacy in carefully selected patients with increased tumor burden.

NK cell therapy

Natural killer (NK) cells are cytotoxic lymphocytes that play a critical role in innate immunity. NK cells do not cause graft-versus-host disease, which makes them promising candidates for cancer treatment. Treatment of relapsed/refractory acute myeloid leukemia with haploidentical NK cells and recombinant human interleukin-15 induced CR in 32% of patients [102]. Clinical trials are currently evaluating CAR-NK cells in hematologic (NCT03056339, NCT00995137) and solid (NCT03656705, NCT03383978) malignancies.

Personalized vaccines (vaccinomics)

The accumulation of somatic mutations in cancer can generate cancer-specific neo-epitopes. Autologous T-cells often identify these neo-epitopes as foreign bodies, which makes them ideal cancer vaccine targets. Every cancer has its own unique mutations, but a small number of neo-antigens are shared between cancers. Theoretically, technological advances will soon result in rapid mapping of mutations within a genome, rational selection of vaccine targets such as neo-epitopes, and on-demand production of vaccines tailored to a patient's individual tumor. Alternatively, off-the-shelf vaccines for tumors with shared epitopes might also be exploitable.

Several personalized vaccines are currently being evaluated in clinical trials [103,104]. For example, investigators used computational prediction of neo-epitopes to design personalized RNA mutanome vaccines for patients with metastatic melanoma [103]. Two of the five patients treated had objective responses to the vaccine alone, while a third patient had a CR to treatment with the vaccine combined with PD-1 blockade [103]. In another study of vaccine-induced polyfunctional CD4+ and CD8+ T-cells targeting unique neoantigens in patients with melanoma [104], four of six vaccinated patients had no recurrence at 25 months after vaccination [104].

Sipuleucel-T, the first FDA-approved therapeutic cancer vaccine, is produced via *ex vivo* activation of autologous peripheral-blood mononuclear cells by a recombinant fusion protein comprised of prostatic acid phosphatase and granulocyte-macrophage colony-stimulating factor [105]. Sipuleucel-T is used to treat metastatic castration-resistant prostate cancer on the basis of results of a randomized, double-blind, placebo-controlled phase III trial in which patients who received Sipuleucel-T had longer survival than those who received placebo (25.8 months vs. 21.7 months, respectively; $p = 0.03$) [105].

Challenges and solutions for the optimal implementation of precision medicine

Genomic studies have unveiled the reality of tumors—they are tremendously heterogeneous and complex, and optimized therapy often does not result from classical clinical research and practice models.

Precision medicine studies (Tables 1 and 2) demonstrate the major challenges in designing trials for this new paradigm. First, the rate of matching patients to drugs in these trials ranges from 5% to 49% and is mostly in the 15% to 20% range. Failure to match patients is attributed to (i) enrollment of individuals with end-stage disease, who deteriorate or die early; (ii) use of small gene panels that yield limited actionable alterations; (iii) delays in receiving and interpreting genomic results;

and (iv) difficulty accessing targeted therapy drugs and/or limited drug availability. Some solutions provided by trials with higher matching rates, e.g., I-PREDICT¹² (matching rate, 49%), include: (i) use of clinical trial navigators and medication acquisition specialists; (ii) application of a large NGS panel with > 200 genes; (iii) creation of just-in-time electronic molecular tumor boards immediately upon physician request; and (iv) exploitation of biomarkers to match patients to chemotherapy, hormonal therapy, and immunotherapy (in addition to gene-targeted agents). The majority of these trials [2,3,12,24] have shown improvement in clinical outcomes when treatments are matched to drugs compared to when they are not. Importantly, malignancies have complicated molecular biology, and use of personalized combinations of drugs that address a higher percentage of the aberrations present in an individual cancer is associated with better outcomes than more limited matching [6,7,12,13].

Other major hurdles encountered in the implementation of precision medicine include the following: (i) Potential differences in response to matched therapy depending on histology and/or genomic co-alterations. In contrast to molecular abnormalities that predict tumor agnostic response to treatment (e.g., NTRK fusions, MSI-H) [27,71,73], selected genomic biomarkers are predictive in specific tumor histologies [106,107]. (ii) The heterogeneity, complexity, and constant evolution of genomic landscapes. Due to significant heterogeneity between primary tumor and metastatic sites, molecular profiling of tumor tissue obtained from a single lesion may not always be representative of the systemic disease [108,109]. Additionally, under the pressure of targeted treatments, tumor molecular profile constantly evolves, with emerging resistant clones and new molecular alterations driving disease progression [110,111]. (iii) The need to screen large numbers of patients in order to find specific/rare genomic defects (for instance, NTRK fusions) [27,106,107]. (iv) Incomplete biologic/molecular profiles with which to select therapy; suboptimal technology and resources to understand completely the drivers of cancer in individual patients; (v) Considerable delays in the activation of clinical trials; (vi) differences in the metabolism and adverse effects of study drugs in various ethnic groups; (vii) lack of agreement between assays from different diagnostic companies/laboratories; and (viii) most importantly, lack of access to drugs for patients with limited resources as well as excessive eligibility criteria that rule out large swaths of patients with real-world co-morbidities. Approximately 3–5% of patients with cancer are enrolled on clinical trials and accrual is limited by overly restrictive eligibility criteria and limited access to drugs [112]. ASCO, the Friends of Cancer Research, and the FDA recommended to broaden eligibility criteria to allow more patients to participate in clinical trials and gain benefit from novel investigational therapies [113]; and consequently participants will be representative of the actual patient population, increasing generalizability of the results. Patient enrollment could be enhanced by national and worldwide collaborations, as shown in multi-institutional trials [114,115]. Finally, the Clinical Trials Transformation Initiative (CTTI), has been developed to examine the challenges and propose solutions to improve trial recruitment [116].

Several initiatives might help overcome the challenges introduced by our emerging understanding of cancer biology: (i) molecular profiling (tissue, blood) should be used at the time of diagnosis and during the course of the disease, the latter to monitor response and resistance; (ii) completion of molecular profiling should be expedited; and (iii) bioinformatic analysis should be optimized to include the key drivers of carcinogenesis.

With the current excitement about the promise of immunotherapy, a large proportion of patients are assigned to immunotherapy trials without undergoing molecular profiling or immune marker identification. Although a significant minority of these patients will experience a clinical benefit and prolonged survival, the majority will have disease progression and/or significant adverse events. Therefore, the incorporation of biomarkers into the selection of patients for immunotherapy needs to be optimized.

Finally, the immense potential of real-world data needs to be addressed. Validation of database information can be performed by comparing outcomes of clinical trials that led to approval with those in the database; if outcomes are similar, real-world data can then be used to rapidly predict new applications for medicines.

Conclusions and future perspectives

Remarkable biotechnological advances are transforming cancer care. Tumor and cell-free DNA profiling using NGS, as well as proteomic and RNA analysis, and a better understanding of immune mechanisms are optimizing cancer treatment selection. A major challenge in the therapeutic management of patients with advanced metastatic cancer is the complexity of tumor biology. This complexity is attributed to highly variable patterns of genetic and epigenetic diversity and clonal architecture associated with spatial expansion, proliferative self-renewal, migration, and invasion. The complexity is amplified by the dynamic, Darwinian evolutionary character of cancer cells, which undergo sequential searches for mechanisms to escape environmental constraints. Such cellular evolution involves the interplay of advantageous “driver” lesions, neutral or “passenger/hitchhiker” abnormalities, molecular changes in the tumor cells that increase the rate of other genomic anomalies, and modifications to the microenvironment and immune machinery that alter the fitness effects of other variables [117]. Strategies to address tumor complexity include targeting self-renewing cancer stem cells to overcome their plasticity and adaptability, impacting the microenvironment, and turning cancer into a chronic disease (using cytostatic drugs to suppress cell division and new mutations). The complicated nature of tumor biology is also the result of interactions between the tumor, host, and local ecosystem, including HLA type, genetic polymorphisms, microbiome, immune cell repertoire, and tumor microenvironment [118]. New strategies, some of which now have a proven track record, include gene-directed therapies and a host of immune-targeted approaches (e.g., checkpoint blockade, CAR T-cells, personalized vaccinomics) [118,119].

An overarching theme is that optimized therapy may require the utilization of combinations of drugs and/or strategies that attack the tumor from multiple angles. It is time to recognize the possibility that advanced computer implementation could generate real-world data that expand our understanding of cancer, rapidly identify new treatments, and create personalized drugs or immune therapies.
